Exploring Optimal Strategies
for Dice of Doom

#### Abstract

Dice of Doom is a strategy game similar to Dice Wars and Risk. Since it is a game of chance, finding an optimal strategy can be challenging. In this thesis, we explore optimal strategies for Dice of Doom. The research is divided into two parts. In the first part, different strategies are compared to a greedy strategy. The strategies examined are the random strategy, the return zero strategy, the Monte Carlo strategy, the Monte Carlo Tree Search strategy, and the expansion strategy. These strategies are compared to the greedy strategy using simulations. In the second part, the focus is on determining the probability of winning when both players play optimally. The difficulty is that the game contains cycles, which breaks the brute force method. To solve this issue, policy iteration is applied. This approach resulted in a very effective strategy, which was then compared to the greedy strategy.

In conclusion, this research found a strategy for the game Dice of Doom that is close to optimal. One observation is that the greedy strategy outperforms any of the five compared strategies when there is a maximum number of five dice allowed. However, when only two dice are allowed per tile, the other strategies outperform the greedy strategy. The close-to-optimal strategy was successful against the greedy strategy in both cases. Regarding the probability of winning, we found that the starting player has a slight advantage over the other player. The game becomes more 'fair' as the number of dice allowed on a tile increases.

## 1 Introduction

Table top games have always been enjoyed by many people. It stimulates the brain to come up with better and better strategies to compete against other players. One of those games is Dice of Doom. This game, as explained in the book 'Land of Lisp' [Bar11], is very similar to the classic game Risk. The goal of the game is to own the highest number of tiles on the map. To do this, players have to make calculated decisions and take into account the odds of winning. Dice of Doom introduces gameplay features different from Risk that make the game easier to learn, but hard to master.

### 1.1 Thesis Goal

This thesis explores the optimal strategies for the game Dice of Doom, consisting of two parts. In the first part, a comparison is made between a greedy strategy and other strategies, to answer the question: "How can a computer beat a human player who uses a greedy algorithm to play the game 'Dice of Doom'?" In the second part, the research focuses on the question: "What is the probability that a player wins, given a game state in 'Dice of Doom' when both players play optimally?" With the outcomes of this research, we aim to develop a strategy that is optimal or close to optimal.

### 1.2 Related Work

For the scope of this research, we will be looking at games that are similar to Dice of Doom, and research in those fields. There have been many studies to explore the battle outcomes, strategies, and decision-making processes in games similar to the classic game Risk. In this section a short overview is given about relevant research and key findings of the research.
In [Geo04], the analysis focuses on examining the factors that influence the probabilities of winning battles in the game Risk. The paper provides insights into strategic decision-making by considering various elements, like the troop deployment, dice outcomes, and the impact of different regions. By analyzing battle outcomes, this study shows the dynamics of the game and offers guidance for players aiming to improve their strategies.
In [Blo20], an application of the AlphaZero algorithm to the game of Risk is explored. The authors developed an AI agent capable of learning to play Risk through self-play. By using deep neural networks and Monte Carlo Tree Search, the AlphaZero agent achieved a remarkable performance, surpassing human players. This research shows the potential of using AI techniques to enhance game play and provide challenging opponents for players.
Furthermore, the use of Monte Carlo methods in board games, including Risk, has been extensively studied. The paper [EMAS10] provides an overview of how Monte Carlo (MC) simulations can be used to estimate winning probabilities and evaluate strategies in various games, including Risk. MC simulations involve running numerous random simulations of game outcomes to approximate winning probabilities and find optimal moves. This approach enables players to make better moves based on statistical analysis, contributing to a deeper understanding of the game dynamics.
There was also an analysis of different agents in the game of Risk, as described in [Dro18]. This research compares the performance of four agents, being Knapsack, Angry, Evaluate, and Random, in a two-player version of Risk without neutral factions. The thesis extensively examines the characteristics and strengths of each agent, considering factors such as aggressiveness, planning moves in advance, and the behavior of greedy agents. Based on the analysis, the Angry agent was
the most successful. This study provides insights into agent-based game play and highlights the significance of agent characteristics in determining success in Risk.
In summary, previous research has examined various aspects of games like Risk, including battle outcomes, the application of AI algorithms such as AlphaZero, the use of Monte Carlo simulations, and the comparison of different agents. These studies contribute to a deeper understanding of the dynamics, strategies, and the potential for AI agents. The insights gained from these works, including strategies and algorithms, were used in our research on the game Dice of Doom.
There was no research found that directly involves the game Dice of Doom.

### 1.3 Thesis Overview

Section 2 of this thesis contains the in-depth rule set of the game Dice of Doom. In Section 3 the methodology is described. In this section the implementation of the game is explained, as well as the different strategies, how to obtain the best winning probability, and how to get a close-to-optimal strategy. In Section 4 the results of this research can be found for both the strategies and the probability of winning. In Section 5 the conclusion and further research are described.

## 2 Rules of Dice of Doom

Dice of Doom is a simple game, but some gameplay features within the game are more complex. In this section we explain how the game works and what the rules of the game are. Note that some rules listed below are slightly different from the rules as explained in [Bar11]. In particular, we added some limitations and exceptions to make the research more concrete.

### 2.1 The Basic Rules

We start with a list of basic rules of Dice of Doom. Exceptions are clarified in Section 2.2.

## Setting up the Game

- There are two players, playing against each other.
- There is a hexagonal grid of $5 \times 5$ hexagonal tiles. The tiles are placed in such manner that the complete grid is diamond shaped.
- Each tile on the hexagonal grid is owned by one player.
- On each tile, there is a minimum of one 6 -sided die belonging to the player who owns the tile. Each die has an equal probability of rolling numbers 1 through 6 . There is an upper bound of five dice allowed on a tile, and any additional die on a tile will be removed from the game.
- While setting up the game, the tiles on the board are randomly distributed among the players. This means that the ownership of the tiles is determined randomly, and the number of dice placed on each tile is also chosen randomly. Of course, the number of dice does not exceed the upper bound we just mentioned. It's worth noting that due to this randomness, one player might end up with a significantly greater number of tiles than the other player.
- Although it is not explicitly stated in [Bar11], in our implementation of Dice of Doom, the player with ID 0 (represented by the color red) starts the game. However, in the 2-player version of Dice of Doom, it doesn't matter which player starts, as the ownership of the tiles is randomly assigned.

## The Turn of a Player

- A turn consists of a series of attacks followed by placing reinforcements before ending the turn. The player is required to make at least one attack before placing reinforcements. Both attacking and placing down reinforcements are regarded as moves.
- To initiate an attack, the player must select a tile adjacent to an enemy tile, and this chosen tile must have a minimum of two dice on it. During an attack, the dice stacks on both tiles are rolled independently. The sums of the rolled dice for both players are then compared. If the sum of the attacker's dice is greater than the sum of the defender's dice, the attacker wins the battle. If the sum of the attacker's dice is less than or equal to the sum of the defender's dice, the attacking player loses the battle.
- If the attacker wins, the defending player's dice are removed from that tile and the attacking player now owns that tile. All dice but one are moved to the newly owned tile.
- If the defender wins, the attacker removes all dice but one from the attacking tile. That is, one die remains, and no dice of the defending player are removed.
- After the attack (regardless of the outcome of the attack), the player can choose to make another attack, or place reinforcements and end his turn (the skip option).
- After the completion of a turn, the next player takes the turn.

## Reinforcements

- Before a player can end his turn, he has to place down reinforcements on his tiles. These additional dice can be placed down in any manner, but any dice exceeding the maximum of 5 dice on a tile are removed. When all dice are placed down, the turn ends.
- The number of reinforcement dice that the player must place down is equal to the number of tiles in the player's largest contiguous territory.

## How to Win the Game?

- If a player cannot perform a single attack during his turn, the game ends. This can be the case either if the player does not own any tiles, if the player owns all the tiles, or if all of the tiles that are adjacent to enemy tiles have only one die.
- When the game ends, the player owning the most tiles wins.
- If the numbers of tiles owned are equal, the game results in a tie.

### 2.2 Exceptions

For the game Dice of Doom, there are not many exceptions, as the game is quite straightforward. However, there is one tricky situation that can occur, which is the possibility for a game to continue infinitely. To avoid this issue, a new rule is introduced. If a game of Dice of Doom exceeds 100 turns it results in a tie.

### 2.3 Game Example

This section demonstrates a simple example using the rules of Dice of Doom. The game is played on a $2 \times 2$ board with a limit of two players and five dice per tile. The red player starts the game. The random initialization can be seen in Figure 1, where the numbers on the tiles represent the numbers of dice.

Figure 1: Random board initialization. The red player starts.
The red player begins his turn by attacking the blue player, as seen in Figure 2. Both players roll the dice on his respective tiles. The red player rolls three dice, while the blue player rolls two dice. The sum of the red player's dice is 8 , whereas the sum of the blue player's dice is 7 . Therefore, the red player wins the battle with a higher total. As shown in Figure 3, the red player can now take over the blue tile, leaving behind one die.

Figure 2: The red player attacks the blue player indicated by the white arrow. The outcome of the dice roll is displayed beside the board.

Figure 3: The red player has won the battle and takes over the blue tile, leaving one die behind.
After winning the battle, the red player can attack the other blue tile, but chooses the skip option (end his turn). Now, reinforcements are added to the red player's tiles. The number of dice added is
equal to the total number of tiles in the largest contiguous territory owned by the red player. In this case, it is equal to 3. As depicted in Figure 4, the dice are added to the tiles.

Figure 4: The red player ends his turn and gains reinforcements. A total of three reinforcements are added to the red tiles.

Now it is the blue player's turn. The blue player attacks one of the red player's tiles using the three dice on his tile, against the two dice of the red player. Both players roll their dice. As shown in Figure 5, the blue player obtains a total of 9 , and the red player obtains a total of 9 as well. Since the totals are equal, the blue player loses the battle.

Figure 5: The blue player attacks one of the red player's tiles. The dice show the outcome of the battle.

Since the blue player lost the battle, the dice on the attacking tile are reduced to 1 , as seen in Figure 6. A player needs at least two dice on a tile in order to initiate an attack. This means that he is unable to attack. As the blue player has already attacked during his turn, the player can end his turn. In Figure 7, reinforcements are added to the blue tile, and it is now the red player's turn.

Figure 6: The blue player loses two dice.

Figure 7: The blue player ends his turn, and reinforcements are added. Now it is the red player's turn.

The red player attacks the last remaining tile of the blue player, as shown in Figure 8. The red player rolls three dice and obtains a total of 9 , while the blue player rolls two dice and obtains a total of 6 . With a higher total, the red player wins. Now all dice except for one die move to the newly obtained tile.

Figure 8: The red player attacks the last tile of the blue player. The result of the thrown dice are shown.

Since the red player can no longer attack, he is forced to pass the skip option, as seen in Figure 9. He can place down a total of 4 reinforcements.
The blue player has no remaining tiles on the board, meaning that the blue player can no longer attack. As a result, the game ends. The tiles of both players are counted and compared. In Figure 10, the outcome of the game is shown.

Figure 9: The red player can add a total of 4 reinforcements.

Figure 10: The red player has won the game.

### 2.4 Variations

The game Dice of Doom can also be played with a few variations. These variations can change the way the game is played, and influence the best strategy to play. The different variations mainly deal with the initialization, variables and limits, and reinforcements.
For the initialization in the current game, the ownership and dice on a tile are set randomly. However, this can be varied. One of the variations that we will examine in this thesis, is the random initialization where the numbers of tiles owned by players are (nearly) the same. This way, the games will be more interesting, as there is a smaller probability that the random initialization will result in a nearly finished game. We also vary in the size of the board.
There are also some different variations that will not be considered in this thesis. This includes the shape of the board. This for example can be in a not diamond-shaped lay-out, like a triangle or even the shape of a country. One other variation that can be added, is to merge certain hexagons together, meaning that tiles may have more neighbors than the maximum of 6 neighbors. This way the game looks more like the games Risk and Dice Wars.
The game Dice of Doom has a lot of variables and limits that can be changed. One of the variations that can be created using these limits, is a game with more than two players. There is also an option to change the shape of the dice. All this however, will not be looked at in this thesis. We will, however, be looking at the option to add fewer dice on the board.
Finally the game can be varied in the way that the reinforcements are calculated and distributed. As described in [Bar11], one could also calculate the number of dice that are obtained by attacking, minus one. This means that you get no reinforcements if you have no winning attacks. For example, if the red player has already obtained three dice, and wins an attack in which he obtains an additional two, the red player would have a total of five dice. If the red player now ends his turn, he would get four reinforcements to place down. This will not be looked at in this thesis.
As for the distribution of reinforcements, there are two more variations for the game. The first variation is deterministic. In this version the dice are placed in a deterministic order from left to right and from the top to the bottom. Every tile gets at most one die added to it. The other version is the weighted random distribution. In this version, the dice are randomly distributed over the tiles, but the tiles with more dice, have a bigger probability to get an additional dice.

## 3 Methods

In this section of the thesis, we discuss our implementation of the game Dice of Doom. The research requires the development of three distinct components: the base game, strategy simulations, and an algorithm to calculate the probability of winning. All of the code is written in the programming language $\mathrm{C}++$.

### 3.1 Implementation of the Game

To implement the game Dice of Doom, we make use of object-oriented programming (OOP) due to the ease of separating the game's components and the minimal need for shared information.
The game consist of the following components:

- The game board
- The game loop
- The different strategies
- The variables and upper bounds

A brief explanation is provided for each component below, along with an explanation of how these components interact with each other.

### 3.1.1 The Board of the Game

The board component keeps track of the length and width of the board, as well as who owns which tile and how many dice each tile has.
Besides storing information, the board component also has a few functionalities that are used by the other components. These functionalities mainly consist of the moves a player can make, adding reinforcements, and calculating the winner of the game.
There are also a lot of functionalities to make the game easier to understand for a human player. For example, the ability to print the current board lay-out and the moves the current player can execute.
Other functionalities are not necessarily needed for the base game, but are used by different strategies later on in the research. These are functionalities like the probability a move has of succeeding.

### 3.1.2 The Game Loop

In order to play the game, a game loop is required. This component is responsible for determining the moves of a player using a certain strategy, passing the turn to the next player, and ending the game when a player cannot perform any actions.
The game loop component uses the board component as a foundation to build on, as the game requires a board to function. Furthermore, the board is used to execute the players' moves and determine the winner of a game.
This component also keeps track of the current player's turn and the current turn that the players are playing. Situations may arise where the game enters an infinite loop, as explained in Section 2.2. To prevent these infinite games from occurring, the game results in a tie after one hundred turns.

### 3.1.3 The Different Strategies

In order to play the game, we also need a way to execute different strategies. That is why there is a strategy component. This component is used during the game loop to calculate the moves that the player should execute according to the chosen strategy.
For the base game, there are only two different strategies: the human strategy and the greedy strategy. More strategies can easily be added for the first research question, as we see in Section 3.2.

## The Human Strategy

The human strategy consists of a human player who uses his insight to make a move. This strategy requires the game to be visualized and shown to an actual human. However, this strategy is not used in this thesis due to the challenges of conducting a significant number of experiments involving human participation.

## The Greedy Strategy

The other strategy is the greedy strategy. This strategy uses a greedy approach to calculate the best move given a game state. The approach only looks one step into the future. To determine the best move, the strategy examines all possible moves the player can make on the current board.
In order to find the best score for each move, the strategy looks at the following variables: the probability $p$ of achieving victory in an attack, the number of dice $x$ on the board when winning an attack, and the number of dice $y$ on the board after losing an attack. Using this information, a score can be calculated for every move:

$$
\text { score }=x \times p+y \times(1-p)
$$

The numbers of dice $x$ and $y$ also include the amount of reinforcements that would be gained by passing a skip move after the attack. This way, the growth of the largest contiguous area is also taken into account and rewarded.
After the first move has been made, there is also an option to pass the turn to the next player. The score of this move is equal to the number of dice resulting from adding reinforcements to the current board. This score is used as a lower bound, as executing 'bad' moves makes it easier for the opponent to counter-attack.
The algorithm prioritizes attacking over skipping, as having a larger area at the end of the turn results in more reinforcements. If a move has the same score as the lower bound of the skip option, the turn is passed. Since with the skip option no dice can be lost.
Once all the scores have been calculated, the strategy executes the move with the highest score. A pseudocode description of the greedy strategy is given in Appendix A.

### 3.1.4 The Variables and Limits

In this research, certain variables and limits are used. As explained in Section 2, the game Dice of Doom has predefined variables that are used in our research. These variables include the $5 \times 5$ board, the maximum of five dice on a tile, and the requirement of two dice to initiate an attack. In addition to these limits, a maximum number of turns is required. As described in Section 2.2, there is a potential for the game to continue indefinitely. To ensure computational feasibility, we
added a limit of 100 turns to the implementation. When the 100th turn is finished and there is no winner, the game results in a tie.

### 3.1.5 The Probability of Winning a Battle

In order to calculate the probability of winning a battle, we first need to look at all the possible battles that can happen. As explained in Section 2.1, a player can only attack from tiles that have neighboring enemy tiles and have at least two dice themselves. In general we know that the attacker can attack with $a$ dice, and the defender can defend with $b$ dice, with $a \geq 2, b \geq 1$, and $a, b$ are integers.
Once the combinations of $a$ and $b$ involved in possible attacks are identified, we need to calculate the probability of winning these attacks. The condition for winning is that the sum of $a$ dice must be greater than the sum of $b$ dice. This can be expressed as the following probability:

$$
P(\operatorname{Sum}(a)>\operatorname{Sum}(b))
$$

Here, the formula $\operatorname{Sum}(z)$ represents the sum obtained by rolling $z$ dice randomly and summing the numbers shown on the top faces of the dice. The notation $P(X)$ denotes the probability of event $X$ to occur.

## The Math behind the Winning Probability

Given the probability formula, we can express it in a different form. This involves summing the probabilities where $\operatorname{Sum}(a)$ is equal to a variable $i$, and $\operatorname{Sum}(b)$ is less than $i$, for all $i$ ranging from $a$ to $6 a$.

$$
\sum_{i=a}^{6 a} P(\operatorname{Sum}(a)=i) \times P(\operatorname{Sum}(b)<i)
$$

The following recurrence relation is used to calculate the probability of $P(\operatorname{Sum}(a)=i)$ :

$$
P(\operatorname{Sum}(a)=i)= \begin{cases}1 & \text { if } a=0 \text { and } i=0 \\ 0 & \text { if } i<a \text { or } i>6 a \\ \sum_{d=1}^{6}\left(\frac{P(\operatorname{Sum}(a-1)=i-d)}{6}\right) & \text { if } a \geq 1 \text { and } i \geq a\end{cases}
$$

There are three base cases in this recurrence relation. The first two base cases handle the scenarios where there are zero or one dice. The third base case checks if the number $i$ cannot be obtained with $a$ dice. In the recursive part of the formula, the sum is calculated by throwing one die resulting in the value $d$. Then we evaluate the probability of obtaining the value $i-d$ with $a-i$ dice. This is done for all six possible values $d$. Finally we average over these values. One additional benefit of the third base case is that it also deals with the negative number $i$ and the case where either $a$ or $i$ is zero, both of which can occur in the recursive step.
Using this recurrence relation, we can also calculate the probability $P(\operatorname{Sum}(b)<i)$ as follows:

$$
P(S u m(b)<i)=\sum_{j=b}^{i-1} P(\operatorname{Sum}(b)=j)
$$

## The Implementation

At the start of the program, all the probabilities are calculated and stored in a table. This table is used for the required probabilities in different strategies. The table is indexed by the numbers of dice, denoted as $a$ and $b$, both with a limit corresponding to the maximum number of dice allowed on a tile.
To efficiently compute the probabilities, we employ the bottom-up dynamic programming approach with the recurrence relation $P(\operatorname{Sum}(a)=i)$. We use a 2 D array of size $(a+1) \times(i+1)$ and iteratively calculate the probability for each entry of a row based on the values computed in the previous row. By evaluating the value at index $(a, i)$, we obtain the probability $P(\operatorname{Sum}(a)=i)$, which is then returned as the result.
The remaining functions used to calculate the probability $P(\operatorname{Sum}(a)>\operatorname{Sum}(b))$ follow the formulas mentioned earlier. The resulting probabilities are given in Table 1, where the attacking tile contains $a$ dice and the defending tile contains $b$ dice, with a maximum of five dice allowed on a tile. The row corresponding to attacking with one die is included to display the odds, but it is not a valid scenario in the game since a player needs at least two dice to start an attack.

|  | b | 1 | 2 | 3 | 4 |
| :--- | :--- | :--- | :--- | :--- | :--- |
| a |  |  |  | 5 |  |
| 1 | 0.416667 | 0.0925926 | 0.0115741 | 0.000771605 | $2.14 \mathrm{E}-05$ |
| 2 | 0.837963 | 0.443673 | 0.152006 | 0.0358796 | 0.00610497 |
| 3 | 0.972994 | 0.778549 | 0.453575 | 0.191701 | 0.0607127 |
| 4 | 0.997299 | 0.939236 | 0.74283 | 0.459528 | 0.220442 |
| 5 | 0.99985 | 0.98794 | 0.909347 | 0.718078 | 0.463654 |

Table 1: The probability $P(\operatorname{Sum}(a)>\operatorname{Sum}(b))$ when attacking with $a$ dice and defending with $b$ dice.

### 3.2 Strategies

As described in Section 3.1.3, we have defined a greedy strategy for the game Dice of Doom. For the first research question, we need to find a strategy that can beat the greedy strategy. In order to achieve this, we examine multiple strategies: the random strategy, the return zero strategy, Monte Carlo strategy, Monte Carlo Tree Search strategy, and the expansion strategy. These strategies are described below.
Note that each strategy has a random component. Once a move has been selected, executing the move involves rolling the dice. Depending on the outcome, the move may result in either a winning move (gaining a tile) or a losing move (losing dice). There is also the possibility to pass your turn after making one or more attacks. It is good to note that the newly obtained tiles are also taken into consideration for each of the strategies when deciding which move to make next. Furthermore, the strategies have no influence on how the reinforcements are placed.
The reason for using the greedy algorithm in our research is the small computational power required. Since a greedy algorithm looks only one step ahead, it requires fewer calculations compared to algorithms that consider multiple steps or the full game tree. It is also more user-friendly, as with some effort the greedy strategy can be applied by a human player. By conducting experiments, we aim to determine the best strategy to use for playing the game.

### 3.2.1 Baseline

In this research, we use the greedy strategy as our baseline. When we let the greedy strategy play against itself, we can observe if any apparent patterns exist. We may use such patterns to gain further insight into the results obtained when comparing the other strategies against the greedy strategy.

### 3.2.2 Random Strategy

For the random strategy, a list is constructed containing all possible moves a player can make. If the player has already made a move, which implies that he can decide to end his turn, then a skip option is added to the list with an equal probability of being selected as any other move. Once the list has been constructed, this strategy randomly chooses a move from the list, which is then executed on the board.
After a move is made, the strategy revisits all possible moves and reconstructs the list. This process continues until either the skip option is chosen or there are no more available moves. In the latter case, the turn is automatically passed, and the next player takes his turn.
The reason for using the random strategy is to measure the trade-off between exploration and exploitation factors. While the greedy strategy calculates a local optimum (exploitation), the random strategy makes moves at random (exploration). Additionally, the random strategy serves as a baseline for comparing against the greedy algorithm. If the greedy strategy significantly outperforms the random strategy, it implies that the greedy algorithm can be considered a valid strategy, as it represents an improvement over random moves.

### 3.2.3 Return Zero Strategy

The return zero strategy is a straightforward approach that selects the first available move. This move is determined in a deterministic manner by iterating over the tiles from left to right and top to bottom. If a valid move is found, this strategy selects and returns that move. If there are no more possible moves on the board, and at least one move has already been executed, the strategy skips the turn.
The idea behind this algorithm is related to the distribution of reinforcements. In one of the implementations, reinforcements are distributed deterministically from left to right and top to bottom. This aligns with the order in which the possible moves are constructed. On might expect that executing moves on tiles more likely to receive reinforcements results in an increase in the number of reinforcements obtained by the player.

### 3.2.4 Monte Carlo Strategy

In our implementation of the Monte Carlo (MC) strategy, we follow a five-step process similar to the one described in [Ade14], but with a slight difference. Instead of running a single instance of Monte Carlo on a given board, we run one Monte Carlo instances for each of the possible moves $n$, as outlined below:

1. Pseudo-Population Selection: We start by selecting a pseudo-population or model that represents the true population of interest. In our case, the model consists of the 2 boards obtained after executing move $n$ on the root board, or 1 board if move $n$ is the skip move.
2. Random Board Selection: From the chosen pseudo-population, we randomly select one of the boards by executing move $n$ on the root board, which results in either a losing or winning move.
3. Statistical Value Calculation: Using the obtained board, we simulate the game using the random strategy until it reaches a terminal state (win, loss, or tie). We only consider the outcomes of winning simulations as our main focus is on identifying moves that lead to successful outcomes and maximize the probabilities of winning. An example of this step is illustrated in Figure 11, where "move 1" results in a losing board state. However, despite the initial setback, the simulation leads to a win, which is then added to the statistical value.
4. Iterative Trials: We repeat steps 2 and 3 for a specified number of trials $(\mathrm{N}=100)$ to gather a collection of statistics for move $n$.
5. Calculation of Statistic: Using the collected statistics from the N trials, we calculate the value for the statistic of interest for move $n$.

After calculating scores for every move using the Monte Carlo algorithm, we compare the scores and execute the move with the highest score. This process continues until the skip option is selected or there are no more possible moves.
The advantages of the Monte Carlo algorithm, as explained in [Ade14], are its straightforwardness and its ability to approximate the optimal solution. We chose this algorithm because of these reasons.

Figure 11: An illustration of a single simulation where executing move 1 on the root board results in a losing move. The simulation results in a win for the player.

### 3.2.5 Monte Carlo Tree Search Strategy

AlphaGo Zero [EMAS10] is an AI program designed for playing the game of Go. One of its key components is the Monte Carlo Tree Search (MCTS) algorithm, which differs from the regular Monte Carlo algorithm in an important way: it focuses on exploring the most promising paths instead of random paths. The MCTS algorithm can be applied to various games.
To initialize the MCTS algorithm, a tree is constructed with a single node as the root. This node contains information such as the total number of games won and played, as well as game-specific details like player ID and the next move to be made. The tree is then expanded using the following steps, as illustrated by Figure 12:

1. Selection: The optimal path from the root to a leaf node is chosen. At each node $V$, the best child is determined using the Upper Confidence Bound (UCB) formula:
$\mathrm{UCB}=\left(C_{\text {wins }} / C_{\text {games }}+0.5 \times \sqrt{\frac{\log V_{\text {games }}}{C_{\text {games }}}}\right) \times C_{\text {chance }}$
In the UCB formula, the first part represents the number of games won when simulating from the child node ( $C_{\text {wins }}$ ) divided by the number of games simulated from the child node ( $C_{\text {games }}$ ). The second part of the formula involves the number of games simulated from the node $V$ $\left(V_{\text {games }}\right)$ and the number of games simulated from the child node $\left(C_{\text {games }}\right)$. The resulting value is then multiplied by the probability of the move leading to a winning attack $\left(C_{\text {chance }}\right)$. If no games have been simulated from the child node, the UCB receives a default score of 10 to prioritize unexplored paths over known paths.
2. Expansion: Once a leaf node has been selected, it checks if the leaf is already in a final game state. If so, expansion and simulations are skipped. Otherwise, all possible moves from the current game state are computed, and a new leaf is added to the tree for each move.
3. Simulation: From the newly added leaf nodes, a random leaf node is chosen, and a predefined number of simulations are performed. Each simulation applies the Monte Carlo algorithm, starting with the selected move and then using the random strategy until the end of the game. After completing all simulations, the child node is updated with the number of games won and the number of games simulated.
4. Backpropagation: The results obtained from the child node are propagated up the tree. The parent node's total number of wins and total number of simulations are updated accordingly. In our implementation, the values in the backpropagation process are multiplied at each step by the probability of reaching the move from that ancestor. This backpropagation continues until it reaches the root node.

Figure 12: Steps involved in the Monte Carlo Tree Search algorithm.
The loop described above is repeated for a fixed number of iterations. After this, the best move is selected based on the total number of simulations performed for each move, rather than the win to total games ratio. This is because the selection phase already accounts for the best possible score using the UCB formula. Therefore, the move with the highest number of simulations is chosen. The process continues until the skip option is selected or no more moves are available.
During the selection phase of the MCTS algorithm's loop, there is a small issue: the construction of the tree does not explicitly consider losing moves and assumes that all moves leading to the optimal game state are winning moves. This decision was made based on AlphaGo's approach, which did not factor in the probability of winning a move but focused on games without probabilities, such as Go and chess.
In our implementation, we initially considered both winning moves and losing moves by simulating them. However, we found that including losing moves did not significantly improve the results compared to the greedy strategy. To maintain simplicity and stay closer to the original algorithm, we decided to exclude losing moves from further consideration in this strategy. Additionally, we experimented with slight changes to the algorithm, which resulted in equal or worse outcomes, which made us decide to stick as closely as possible to the original algorithm.

### 3.2.6 Expansion Strategy

The expansion strategy is similar to the greedy strategy in that it only looks one move ahead. However, the score calculation for a move is different. Instead of considering the average number
of dice that can be obtained, it focuses on the average increase in the size of the largest cluster of tiles achievable with a move. Figure 13 illustrates the difference between the greedy algorithm and the expansion strategy. The greedy algorithm selects the move with a winning probability of approximately $99 \%$, depicted by the white arrow labeled by number 1 . This move is favorable for the greedy strategy since it maximizes the number of dice obtained while also looking at the possible reinforcements:

$$
\begin{gathered}
\text { score }_{1}=(38+13) \times 0.99+(35+12) \times 0.01=50.96 \\
\text { score }_{2}=(38+14) \times 0.74+(35+12) \times 0.26=50.7
\end{gathered}
$$

This scoring formula for the greedy strategy is explained in Section 3.1.3.
However, the expansion strategy makes a different move, indicated by the white arrow labeled by number 2. Although this move may not result in the largest number of dice, it does result in the largest contiguous territory:

$$
\begin{aligned}
& \text { score }_{1}=13 \times 0.99+12 \times 0.01=12.99 \\
& \text { score }_{2}=14 \times 0.74+12 \times 0.26=13.48
\end{aligned}
$$

This strategy continues by prioritizing moves that expand the largest territory. If there are multiple territories of equal size, the algorithm treats moves that expand any of these territories equally. If no further moves are available to expand the largest territory, the strategy skips the turn. If the skip option is not yet available, meaning that no moves have been made yet, the strategy executes a random move and checks if any new moves can increase the largest area. If this is not the case, the turn is skipped, after all.

Figure 13: A $5 \times 5$ board illustrating the difference between the greedy strategy (1) and the expansion strategy (2).

The reason for choosing this strategy is to examine the relative importance of having a larger contiguous territory versus possessing more dice. If there is a significant difference, the player can adjust his strategy accordingly and focus on one of the two options. If there is no significant difference, the player can select the strategy that he finds easier to use.

### 3.3 Probability of Winning

In the second part of this research, we examine the winning probabilities of a player in the game states of Dice of Doom, assuming both players play optimally. In this part, we define a game state as a combination of the skip option, the current player and a possible board state that can be created given a size of the board, the number of players, and the maximum number of dice that can be on a tile. For our analysis, we have set the number of players to two and the maximal number of dice to five, as described in Section 2.1. We have chosen these values to ensure computational feasibility. However, these numbers can be changed in our method and are not fixed values. Furthermore, unlike the previous section about the strategies that used a limit of 100 turns for a game, we do not use this restriction here, since for a given game state, we cannot determine how many turns have already been played to reach that state.
To implement the optimal play of both players, we use a strategy similar to the Minimax method described in [MSZ13]. Unlike the greedy strategy, this approach considers the entire game tree and selects the best path.
In this method, we also consider the probability of a game ending in a tie. This factor is influenced by the different board sizes we test in this method. Since there is no tiebreaker in this game, no points are added to the probability of winning or losing when a tie occurs. Therefore, the probability of a tie must also be calculated.
Additionally, there is a possibility that the game continues indefinitely, which presents a challenge to calculate the exact probability and introduces uncertainties. In this section, we address this issue and suggest a solution to reduce the probability of uncertainties to zero.

### 3.3.1 Total Combinations of the Board

To compute the winning probabilities, we need the possible board combinations, which include all possible ways to distribute dice and assign ownership to each tile. Each tile has an owner (red or blue) and a number of dice (ranging from 1 to 5 ).
To construct the formula for calculating the total number of board combinations, we also need to consider whose turn it is on a given board and whether the skip option is available. We assume that it is always the turn of the red player, as there is always a mirrored version of any given board where the ownership of the red and blue players is reversed. This means that the new red player in the mirrored board was the old blue player. Therefore, we have not considered the current player in the formula. Regarding the skip option, which indicates that a player has already attacked during his turn, there is no simple way to compact this. While there are certain board states where the skip option cannot be achieved, calculating these states precisely is difficult, and they represent only a small portion of the total combinations. Taking all this information into account, the general formula for calculating the total number of board combinations is as follows:

$$
\text { total }=\left(M_{p} \times M_{d}\right)^{(w \times h)} \times 2
$$

In this equation, $w$ and $h$ represent the width and height of the game board, respectively. $M_{p}$ represents the number of players, and $M_{d}$ represents the maximum number of dice per tile. The multiplication by two accounts for the availability of the skip option.
For the board used in the game Dice of Doom, this equation results in a total of 2 septillion $\left(10^{25} \times 2\right)$ board combinations.

### 3.3.2 How to Implement

To calculate the probability of winning, we employ the brute force algorithm, which involves examining all possible moves for a given board. This algorithm uses a game tree, where the leaf nodes represent final game states in which the player either wins, loses, or ties. At each node in the tree, the player can choose which move to make. The root of the tree corresponds to the starting game state for which we want to determine the probabilities.
When making optimal moves at the nodes of the tree, we select the move that obtains the highest probability of winning by examining the probabilities of winning of the node's children. The winning probability of the selected move is then stored in the current node. This process continues until the root of the tree contains its win probability.
To store the probabilities of winning, losing, or ending in a tie, we use a data structure that holds all three values. This data structure is returned by the brute force algorithm.
As explained in Section 3.3.1, we assume that in every state, the turn is for the red player. Of course, this assumption does not accurately reflect real gameplay. To correctly compute the win probabilities, we simply flip the ownership of each tile at the end of each turn. The old blue player, who now possesses the mirrored red tiles, can start his turn.

### 3.3.3 Board Conversion

To convert a given game state into an encoding, we examine the board state. By considering the width and length of the board, along with the ownership and number of dice for each tile, we can encode the current board. The conversion algorithm uses a variable $e$, initialized to 0 , which will eventually hold the final encoding. We iterate over the tiles and apply the following formula:

$$
e=\left(e \times M_{p}+n_{p}\right) \times M_{d}+n_{d}
$$

In this formula, $M_{p}$ represents the number of players, $n_{p}$ represents the owner of the tile, $M_{d}$ represents the maximum number of dice, and $n_{d}$ represents the number of dice on the tile. The iteration over the tiles continues until all tiles have been processed. At the end, the resulting encoding $e$ represents a number ranging from 0 to the maximum number of possible combinations divided by 2 .
It is important to note that this encoding specifically aims to retrieve the board state for a given board configuration. However, it does not account for the skip option. To incorporate the skip option into the game state, the following formula is used:

$$
e=e \times 2+s
$$

Here, $s$ represents the availability of the skip option, which is represented as either 0 (false) or 1 (true).
During the decoding of the game state, the first step involves checking whether the the skip option is available by checking if the encoded number is odd or even. After obtaining the skip option, the integer $e$ is divided by 2 .
Using this remaining $e$, we can reconstruct the original board state by reversing the encoding process. The decoding continues until reverse iteration is complete and $e$ becomes 0 . This signifies the completion of the encoding process.

### 3.3.4 Array of Probabilities

To speed up the process of calculating the probability of winning, we introduce an array that stores the probabilities for each board state. In this array, each index corresponds to the encoding of a specific game state, while the value at that index represents the winning probability for that game state.
During the calculations of the winning probability for each game state, we can now look up previously calculated game states. If the value is known, it can be used as the winning probability instead of calculating it again.
It is worth noting that out of all possible board combinations, a small portion is already in a final state. This portion is typically around $10 \%$ to $20 \%$, depending on the size of the board. For these board situations, the probabilities are relatively easy to calculate.

### 3.3.5 Problem of Cycles

There is a significant problem with this brute force method to compute the win probabilities. For certain game states, the method does not halt. This means that somewhere in the brute force search space, there are loops. These loops are created by a sequence of specific moves that result in the original game board, as illustrated in Figure 14. One option is to end the game after playing a certain number of turns. This ensures that the loop eventually ends. However, this would leave a lot of uncertainty for larger game boards. Instead, we discuss two other methods to deal with these loops.

Figure 14: An example of a loop in a $1 \times 2$ board situation.

### 3.3.6 Conversion to Absorbing Markov Chains

We may approach these loops by considering them as Absorbing Markov chains [KS76]. In short, a Markov chain is a countable set of states connected to each other with certain probabilities. The
introduction of absorbing states turns a Markov chain into an absorbing Markov chain. Absorbing states possess a special property: instead of transitioning to another state, they transition to themself with a $100 \%$ probability, essentially acting as black holes. For every non-absorbing state, there must exist a path from that state to an absorbing state.
In our case, we can view the game loop as a Markov chain, because there are a countable number of states, as described in Section 3.3.1, and each game state has a probability of transitioning to another game state, as described in Section 3.1.5. For final game states, we can assign a transition to itself with a $100 \%$ probability, making them absorbing states. This way, all states adhere to the definition of a Markov chain.
Since the absorbing states represent the final game states and for every game state, there exists a path to a final state, we can conclude that the game can be represented as an absorbing Markov chain. Additionally, we introduce two new labels apart from absorbing and non-absorbing. One of the labels used is called 'known', which is defined by either being an absorbing state with a known probability of winning or a state where all possible children are known. If all the children of a state are known, the probability in the current state can be calculated. The other label is called 'unknown', which occurs when one or more of a state's children are unknown. The optimal winning probability of the state cannot be calculated if at least one of the children remains unknown. Such states consist of those in a loop or those dependent on the win probability of a state in a loop. Figure 14 shows an example of these states being in a loop, where not all children are known, and thus the optimal winning probabilities cannot be assigned to them.
There are ways to solve absorbing Markov chains. However, those methods cannot be simply applied to our game tree. In some cases, multiple cycles are merged, resulting in a node in the cycle that has two or more paths that eventually lead back to itself, as illustrated in Figure 15. The graph shows state A leading into states B and C, and both B and C lead back into A. Since B and C are both dependent on state A, they are both unknown. This causes the problem of not knowing which move is the optimal move from state A. We did think of a way to solve this problem, which involved trying both unknown moves and seeing which of the two gave more optimal results. However, for a $2 \times 2$ game board, the number of states similar to state A is around 300 . Which meant that we would have to check an impractically large number of possibilities.

Figure 15: Cycle problem: What is the best move for state A?

### 3.3.7 Policy Iteration

To avoid the complexity of trying to calculate the exact probabilities in case of cycles, we use the policy iteration method as described in [How60]. This method allows us to achieve a close-to-optimal result through an iterative process. The method consists of multiple iterations. In the first iteration, the probabilities of all possible game states where the red player starts are initialized. In the following iterations, new probabilities for the states are calculated using the children of the given states.
For the initialization, the value is calculated as follows:

$$
v_{0}(k)= \begin{cases}1 & \text { if the red player wins } \\ 0 & \text { otherwise }\end{cases}
$$

That is, for each state $k$, it is checked if the red player has won in that state. If he has, the value of $v_{0}(k)$ is set to 1 , indicating a $100 \%$ winning probability in that state. If it is known to be a losing state or a tie, the winning probability is set to 0 . If the node is not a final state, its value is also set to 0 . In each subsequent iteration, we determine the maximum value among the children of the current node $k$ and calculate the probability of reaching that specific node.

$$
v_{n}(k)=\max _{o} \sum_{l} P_{k, l}(o) \times v_{n}(l)
$$

In this formula, $n$ is the current iteration, o represents all possible moves for state $k$, and $l$ represents all game states. The value of $P_{k, l}(o)$ is the probability that the player transitions from state $k$ to state $l$ using move $o$. This probability is then multiplied by the probability of state $l$ from the previous iteration. The sum of all $P_{k, l}(o)$ always adds up to 1 for a fixed $k$.
If these iterations were repeated infinitely, the system should converge to a situation where:

$$
v^{*}(k)=\max _{o} \sum_{l} P_{k, l}(o) \times v^{*}(l)
$$

Here, the probability $v^{*}(k)$ is solely dependent on $v^{*}(l)$ in the same iteration, making it the final answer.
However, there are some limitations to this method. First, most of the nodes will remain at a probability of 0 for the first iterations. At the start, only the final states are known, and over the iterations, that information propagates to the other nodes. Additionally, this method can be computationally expensive for large board sizes. As the board size increases, so does the number of states in the Markov chain, the number of possible moves for a state, and consequently, the number of iterations needed to obtain a more accurate result. Another limitation is that, for our implementation of the board game, the reinforcements must be placed in a deterministic manner. Otherwise, it becomes very complex to determine the new board state after a skipping move.
In our implementation, we made some adjustments to this method. First, to calculate the best possible move from a given state $k$, we only examine the states that can be reached from that state, rather than considering all game states $l$. Second, if a state becomes 'known' in iteration $n=i$, it is skipped in all iterations $n>i$. After a large number of iterations, only the states that are either part of a cycle or dependent on a cycle remain unknown. In our method, we chose to perform a total of 100 iterations to obtain an accurate result. In practice, we found that already after around 20 iterations for a small board size, the system had somehow converged.

### 3.4 Optimal Strategy

In addition to the strategies described in Section 3.2, we introduce a close-to-optimal strategy based on the method outlined in Section 3.3. The reason it is referred to as close-to-optimal, rather than simply optimal, is because the method approximates the optimal strategy through a number of iterations. If only a small number of iterations is used, the strategy may not perform optimally. This close-to-optimal strategy relies on the winning probability in every game state. It determines one of the optimal moves by calculating the weighted average win probabilities of the winning and losing moves, maximizing this value. Additionally, the skip option is used as a baseline for comparison whenever it is available. In our case, the optimal move refers to the move with the highest win probability.
The structure of this strategy is relatively simple compared to other strategies. At the beginning of the game, it calculates the best move and its corresponding winning probability for all possible states, storing these values in a lookup table. Once the table has been constructed, the game can start. For any given game state, the player can simply consult the lookup table using the current board lay out and the skip option, and execute the best move suggested by the lookup table.
This method offers several advantages. In addition to its accuracy, an advantage is that the lookup table only needs to be calculated once. After creating the tables for various games with different parameters, they can be reused across multiple matches. Although this lookup table can be applied to other strategies as well, it neglects the random element present in most strategies.
This method also has a serious disadvantage. As mentioned in Section 3.3.1, the original game has an enormous number of 2 septillion game states. Calculating and storing the probability for each state over many iterations is practically infeasible. Therefore we only experiment with smaller board sizes.

### 3.5 Simulations

To obtain answers to the research questions, we need to generate results through simulations. In the first part of the experiments, we focus on comparing the greedy strategy to other strategies. In the second part, we analyze the probability of winning and how it varies with different limits and board sizes.

### 3.5.1 Strategies

The different strategies are compared to the greedy strategy. To achieve this, we simulate a total of 100.000 games (if possible), and determine which of the two strategies wins more games. To ensure fairness in the simulations, we alternate the starting player throughout the simulations, starting with the greedy strategy.
At the end of the simulations, we obtain the results, which include the number of wins, losses, and ties. As explained in Section 2.2, a game that exceeds 100 turns are also considered a tie.
Regarding the experiments, we examine variations in board sizes, board initialization, maximum number of dice, and reinforcement types. The chosen board sizes are as follows: $1 \times 2,2 \times 2,2 \times 3$, $3 \times 3,3 \times 4,4 \times 4$, and $5 \times 5$. For board initialization, we use the two methods described in Section 2.4: random and random but with an equal number of tiles $( \pm 1)$ for both players. The maximum number of dice on a tile is set to two, respectively five. The reinforcement types used, as described in Section 2.4, are random, deterministic, and weighted random.
If the simulations become too time-consuming for any of the experiments, the total number of games played is reduced to 10.000 . If even that proves to be time-consuming as well, further reductions in the number of games is made. However, this may lead to less precise results, although it may still provide insights into differences between the two strategies.
For the strategy that is created by taking the close-to-optimal approach from Section 3.4. We only use the deterministic distribution, since it meets the method's requirements.

### 3.5.2 Probability of Winning

The second part of the simulations focuses on the probability of winning. We conduct two experiments using the lookup table. The first experiment involves determining the average win probability, which helps us assess whether it is advantage to be the starting player. In the second experiment, we compare the optimal move to the greedy move. This allows us to determine whether the greedy algorithm is optimal.
To calculate the average win probability, we use the array of probabilities explained in Section 3.3.4. This table stores the winning probability, losing probability, and tie probability. By averaging these values across all game states, we can calculate the average win probability.
For comparing the optimal move to the greedy move, we also use the lookup table. As described in Section 3.4, the lookup table contains the win probabilities from which we can deduce the optimal moves. For each possible game state in which you can make a move, we collect the win probability of the move made by the greedy strategy and the win probability of the optimal move. Then, we separately sum up these two probabilities. If the sum of probabilities are identical, we know that the greedy algorithm is optimal. If the sum of probabilities of the optimal strategy is higher than that of the greedy strategy, we know that the greedy strategy is not optimal. We assume that the greedy strategy does not outperform the optimal strategy.

In this experiment, we also include the random strategy. This strategy acts as a baseline. For every game state, we take a random move and sum the probabilities of that move. Just like we did for the greedy strategy. We assume the sum of the random strategy to be lower than both the greedy strategy and the close-to-optimal strategy.
For the experiments, we examine variations in board sizes and the number of dice. The selected board sizes are as follows: $1 \times 2,2 \times 2,2 \times 3,3 \times 3,3 \times 4,4 \times 4$, and $5 \times 5$. The maximum number of dice on a tile is set to two, respectively five.

## 4 Experiments

To evaluate our methods, we conducted simulations as described in Section 3.5. The experiments consisted of two parts: testing different strategies (Section 4.1) and analyzing the probability of winning (Section 4.2). The results of both experiments are described below.

### 4.1 Strategies

As explained in Section 3.2, we compared our strategies to the greedy strategy. There are six strategies, including the close-to-optimal strategy described in Section 3.4. We analyzed the results of these strategies and their performance to the greedy strategy. If any significant positive results are observed in favor of the competing algorithms, we can conclude that there is a strategy that can beat a human player using the greedy algorithm.

### 4.1.1 Baseline

For the baseline, we compared the greedy strategy to itself. The results, shown in Table B.1.1, yield several interesting observations. When the maximum number of dice was reduced to two, the number of ties increased. We also noticed a slight improvement in the number of wins when we used non-deterministic reinforcement types for the greedy algorithm. Additionally, more ties occurred when the board initialization resulted in an equal number of tiles for both players.

### 4.1.2 Random Strategy

The random strategy selects a move randomly. When comparing this strategy to the greedy strategy, the results shown in Table B.1.2 lead to some interesting findings. One such finding is that the random strategy seems to outperform the greedy strategy for smaller board sizes and when the maximum number of dice is two. This is not the case for reinforcement type 2. However, the greedy strategy makes clearly outperforms the random strategy when the maximum number of dice allowed on a tile is set to five. Additionally, there are more ties when we use non-deterministic reinforcement types.

### 4.1.3 Return Zero Strategy

For the return zero strategy, which always selects the first move in the list, the results are presented in Table B.1.3. When compared to the greedy strategy, the return zero strategy shows slightly better performance than the random strategy. For this strategy, as for the random strategy, we observe that it outperforms the greedy algorithm when the maximum number of dice is reduced to two. In all the other situations, the greedy algorithm clearly outperforms the return zero strategy. Additionally, we see a slight increase in wins for initialization type 2 compared to type 1 . Specifically, for games with a maximum of five dice, the greedy strategy wins more often when there is an equal board initialization compared to a random board initialization. For games with a maximum of two dice, the return zero strategy has a slight advantage with an equal board initialization.

### 4.1.4 Monte Carlo Strategy

The Monte Carlo strategy has fewer results, as shown in Table B.1.4. This is because when the size of the board increases, the number of moves that need to be simulated increases as well. Similar to the previous strategies, the performance of the Monte Carlo strategy varied depending on whether there were two or five dice. Furthermore, we found that this strategy has a lower win to lose ratio compared to the other strategies, and the completely random board initialization seems to have a higher win rate for the Monte Carlo strategy compared to the other initialization type.

### 4.1.5 Monte Carlo Tree Search Strategy

The Monte Carlo Tree Search (MCTS) strategy has even fewer results, as shown in Table B.1.5. As described in Section 3.2.5, the MCTS strategy uses a Monte Carlo search in the leaf nodes of its tree, which is computationally expensive. As the board size increases and the number of possible moves grows, the tree becomes larger. Based on the limited results obtained, we found that the number of wins of the MCTS strategy are slightly better compared to the win rates of other strategies, especially for the maximum of two dice. However, we need more research results to draw a definitive conclusion.

### 4.1.6 Expansion Strategy

The expansion strategy is similar to the greedy algorithm. When comparing it to the greedy strategy, the results shown in Table B.1.6 indicate a significant difference between the two strategies other than the $1 \times 2$ board size. Similar to the random strategy and return zero strategy, the same occurrence is observed for the maximum of two and five dice. Overall, no significant results were found.

### 4.1.7 Close-to-Optimal Strategy

For the close-to-optimal strategy, the results shown in Table B.1.7 indicate that it outperforms the greedy strategy for all board sizes except for the $1 \times 2$ board size, which is as expected. Unlike the previous strategies, the close-to-optimal strategy also outperformed the greedy strategy when the maximum number of dice is five. Some results are missing due to the large number of board combinations for a $5 \times 5$ board, as explained in Section 3.3.1. For this reason it was not possible for us, storage wise, to simulate the bigger board sizes. Additionally, other reinforcement types were not fully explored, as the close-to-optimal algorithm relies on a deterministic reinforcement method. Despite these limitations, the promising results suggest that the close-to-optimal strategy may also outperform the greedy algorithm on a $5 \times 5$ board.

### 4.2 Probability of Winning

In the second part of our research, we examined the optimal win probability and analyzed the performance of the greedy strategy. Since the probability table can only be used during gameplay, it is difficult to experiment with the results. However, we focused on two points of interest: the average win probability of the starting player and how optimal the greedy strategy is. Note that there are some missing data points in the tables for larger board sizes. This is due to the number of board combinations, as explained in Section 3.3.1.

### 4.2.1 Average Win Probability

To calculate the average win probability, as explained in Section 3.5, we took the average of the probabilities from all game states. The results, shown in Table B.2.1, reveal an advantage for the starting player. For both the maximum of five and two dice, the starting player has a higher win probability compared to the second player, with this advantage increasing as the size of the board increases. This advantage also increases when the maximum number of dice on a tile is set to two. Additionally, the maximum of five dice has a significantly lower average tie probability compared to the maximum of two dice.
One other minor detail that can be seen in the table, is that for bigger board states, the probabilities do not sum up to one. As mentioned, policy iteration approximates the win probabilities. This means that for more accurate results, more iterations are required.

### 4.2.2 How Optimal is the Greedy Strategy?

The results regarding the optimality of the greedy strategy are outlined in Table B.2.2. The table displays three different strategies: the close-to-optimal strategy, the greedy strategy, and the random strategy. Additionally, the table shows the number of game states where a move is possible, signifying states that are not final. The percentage of these states in relation to the total number of states is also indicated. The random strategy acts as a baseline to provide further insight into the overall improvements of the greedy strategy and the close-to-optimal strategy.
By comparing the results of the different strategies, we found that the greedy strategy is not optimal. The average win probability of the greedy strategy is not greater than the average win probability of the optimal strategy. In our experiments, we also discovered that the greedy strategy does not have a single move which outperforms the close-to-optimal strategy. This implies that in all states where a move can be executed, the close-to-optimal strategy either equals or outperforms the greedy strategy.
Moreover, the results also show an increase in win probability when the board size increases. Also, when comparing the maximum number of dice that are allowed on a tile, the win probability for the maximum of five dice is lower compared to the win probability when the maximum is two dice. This result is also shared with the previous results of Table B.2.1.
Furthermore, the different strategies do not show a significant difference. This is probably caused by the number of similar moves that all three strategies executed which resulted in the same probability. When a move is made that doesn't match the optimal move, the penalty would not be significant, as the move would still have a probability close to the optimal value.

### 4.3 Conclusion

The main aim of this thesis is to find the optimal strategy for the game Dice of Doom. This goal has been divided into two main parts: different strategies and win probabilities. Furthermore, we implemented the game Dice of Doom in C++. This research contained different strategies, with the greedy strategy being the most important. There were several different problems we encountered when trying to obtain the optimal winning probability. In order to solve these issues, we used policy iteration. Lastly, we conducted experiments, and presented the results.
In conclusion, several key observations can be made regarding the first research question. First, we found that the greedy strategy outperforms every other strategy when the maximum number of dice is five. However, when the maximum number of dice is reduced to two, the greedy strategy seems to be outperformed by every other strategy. We have found no explanation for this yet. Another clear, though not necessarily surprising, result is that the equal initialization method leads to more ties between strategies.
Furthermore, the research revealed no significant difference between the various reinforcement methods used in the experiments. Additionally, when having our baseline, the greedy strategy, compete against itself, we found fewer ties with a maximum of five dice than with a maximum of two dice per tile.
For the second research question, we made several observations. We determined that the greedy strategy is not optimal because there is a difference in win probability compared to the close-tooptimal strategy. Moreover, the starting player has a slight advantage in a game with five dice, while starting with two dice offers a considerable advantage. This suggests that allowing more dice to be on a tile makes the game more fair for both players. Additionally, we found that there were more ties when fewer dice were involved.
Regarding the insights gained from converting the win probabilities, obtained with policy iteration, to a strategy, we found that for smaller game boards, the performance of the greedy strategy and the close-to-optimal strategy remained practically equal. However, as the size of the board increases, the close-to-optimal strategy outperforms the greedy strategy. Also in these simulations, we found that the equal initialization method led to an increased number of ties in both research questions.

### 4.4 Future Work

Since this research is in a relatively new field, focusing on the game Dice of Doom, we have several suggestions for further research. These ideas involve improvements or extensions to the existing research, as well as applying similar methods to other games.
First, the difference in performance of the greedy strategy when the maximum number of dice is reduced to two could be further explored. Conducting a detailed analysis of the game mechanics and evaluating the implementation of the strategy may help uncover the reasons behind this difference. This may result in useful improvements or modifications to the greedy strategy.
As discussed, the impact of the reinforcement methods made no difference. However, further research can explore the reinforcement implementation where players have full control over the placement of their reinforcements. Investigating optimal reinforcement placement and analyzing their impact on the game's outcome can improve the understanding of different strategies for Dice of Doom.
Further research can focus on studying the variations as described in Section 2.4. Analyzing how these variations affect game play, strategy effectiveness, and winning probabilities may lead to
improvements to the original game.
Given the similarities between Dice of Doom and other dice-based strategy games such as Risk and Dice Wars, further research could explore the application of the policy iteration method in these games. Analyzing the performance of policy iteration across different games can show its effectiveness in other strategy games.
While our research mainly focused on two-player games, extending the analysis to multiplayer games could be an interesting direction for further research. Multiplayer games are a lot more complex as they have to take communication between players into account. This can lead to greater diversity of strategies to use against the greedy strategy.

## A Greedy Algorithm

Input: A board layout, the skip option and the current player. Output: The suggested move to execute.

```
Function greedy_strategy():
max = the maximum number of moves possible on the board for the current player
best = 0
curr_best = -1
For i from 0 to max-1:
    winning_board = a copy of the current board
    losing_board = a copy of the current board
    chance = the probability of winning the attack for move i
    Perform a winning move for move i on winning_board
    Perform a losing move for move i on losing_board
    score_win = the number of dice on winning_board + reinforcements
    score_lose = the number of dice on losing_board + reinforcements
    score = chance x score_win + (1.0 - chance) x score_lose
    If score > curr_best:
            curr_best = score
            best = i
If the skip option is available:
    score_skip = the number of dice on the board + reinforcements
    If score_skip >= curr_best:
            best = max
Return best
```

## B Experiment Results

## B. 1 Strategies

Below are the tables displaying the results. In the tables, the letter A represents the wins of the current strategy, while the letter B represents the wins of the greedy strategy. The different types mentioned in the first row of the table indicate the reinforcement types, with Type 1 representing deterministic distribution, Type 2 representing the fully random method, and Type 3 representing the weighted random method. The 'Init' column refers to the board initialization, which can be either random (0) or random with the same number of tiles for both players (1). The 'Dice' column indicates the maximum number of dice per tile in the game, which can be either five dice or two dice. The 'Size' column represents the size of the board, including the width and height.

## B.1.1 Baseline

Both A and B stand for the greedy strategy.

## B.1.7 Close-to-Optimal Strategy

Here, A stands for the close-to-optimal strategy, and B stands for the greedy strategy.

| Type 1 |  |  | Variables |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| A | B | Tie | Init | Dice | Size |
| 44529 | 45221 | 10250 | 0 | 5 | 1x2 |
| 39619 | 39492 | 20889 | 1 | 5 | 1x2 |
| 36347 | 36896 | 26757 | 0 | 2 | 1x2 |
| 22915 | 23286 | 53799 | 1 | 2 | 1x2 |
| 52107 | 46277 | 1616 | 0 | 5 | 2x2 |
| 52124 | 43708 | 4168 | 1 | 5 | 2x2 |
| 50784 | 37670 | 11546 | 0 | 2 | 2x2 |
| 46154 | 26475 | 27371 | 1 | 2 | 2x2 |
| 56182 | 43110 | 708 | 0 | 5 | 2x3 |
| 58688 | 39274 | 2038 | 1 | 5 | 2x3 |
| 66783 | 27627 | 5590 | 0 | 2 | 2x3 |
| 69127 | 16021 | 14852 | 1 | 2 | 2x3 |
| - | - | - | 0 | 5 | 3x3 |
| - | - | - | 1 | 5 | 3x3 |
| 84692 | 15308 | 0 | 0 | 2 | 3x3 |
| 89945 | 10055 | 0 | 1 | 2 | 3x3 |
| - | - | - | 0 | 5 | 3x4 |
| - | - | - | 1 | 5 | 3x4 |
| 74056 | 8577 | 17367 | 0 | 2 | 3x4 |
| 74990 | 4036 | 20974 | 1 | 2 | 3x4 |
| - | - | - | 0 | 5 | 4x4 |
| - | - | - | 1 | 5 | 4 x 4 |
| - | - | - | 0 | 2 | 4x4 |
| - | - | - | 1 | 2 | 4 x 4 |
| - | - | - | 0 | 5 | 5x5 |
| - | - | - | 1 | 5 | 5x5 |
| - | - | - | 0 | 2 | $5 \times 5$ |
| - | - | - | 1 | 2 | $5 \times 5$ |

## B. 2 Win Probability

## B.2.1 Average Win Probability

The table below shows the average win, lose and tie probability for the corresponding board size and maximum number of dice.

| Win | Lose | Tie | Dice | Size |
| :--- | :--- | :--- | :--- | :--- |
| 0.518462 | 0.4177 | 0.0638379 | 5 | 1 x 2 |
| 0.564132 | 0.427367 | 0.00850344 | 5 | 2 x 2 |
| 0.58442 | 0.41484 | 0.00191217 | 5 | 2 x 3 |
| - | - | - | 5 | 3 x 3 |
| - | - | - | 5 | $3 \times 4$ |
| - | - | - | 5 | $4 \times 4$ |
| 0.457404 | 0.334841 | 0.207755 | 2 | 1 x 2 |
| 0.571355 | 0.348744 | 0.0798978 | 2 | 2 x 2 |
| 0.617684 | 0.343413 | 0.0363597 | 2 | 2 x 3 |
| 0.671319 | 0.317899 | 0 | 2 | $3 \times 3$ |
| 0.720518 | 0.264849 | 0.00335683 | 2 | $3 \times 4$ |
| - | - | - | 2 | $4 \times 4$ |

## B.2.2 How Optimal is the Greedy Strategy?

The table below shows the win probabilities for the close-to-optimal strategy, the greedy strategy and the random strategy. It also shows the total number of game states in which you can execute a move, and the fraction of those states compared to all possible states. This is shown for several variations in board size and maximum number of dice.

| Optimal | Greedy | Random | Move | Fraction of Total | Dice | Size |
| :--- | :--- | :--- | :--- | :--- | :--- | :--- |
| 0.562088 | 0.560606 | 0.520434 | 140 | 0.7 | 5 | 1 x 2 |
| 0.587457 | 0.571895 | 0.561298 | 18040 | 0.902 | 5 | 2 x 2 |
| 0.593854 | 0.571531 | 0.560918 | 1933600 | 0.9668 | 5 | 2 x 3 |
| - | - | - | - | - | 5 | 3 x 3 |
| - | - | - | - | - | 5 | 3 x 4 |
| - | - | - | - | - | 5 | 4 x 4 |
| 0.531846 | 0.503339 | 0.475694 | 20 | 0.625 | 2 | 1 x 2 |
| 0.642072 | 0.618661 | 0.576064 | 412 | 0.804688 | 2 | $2 \times 2$ |
| 0.66309 | 0.642069 | 0.603897 | 7300 | 0.891113 | 2 | 2 x 3 |
| 0.690821 | 0.673406 | 0.637657 | 500696 | 0.955002 | 2 | 3 x 3 |
| - | - | - | - | - | 2 | $3 \times 4$ |
| - | - | - | - | - | 2 | $4 \times 4$ |
